## **ABSTRACT**

Chemical composition of fine aerosol particles over the northern Chilean coastal waters was determined on board the US DOE G-1 aircraft during the VOCALS (VAMOS Ocean-Cloud-Atmosphere-Land Study) field experiment between October 16 and November 15, 2008. Chemical species determined included  $SO_4^2$ ,  $NO_3^-$ ,  $NH_4^+$ , and total organics (Org) using an Aerodyne Aerosol Mass Spectrometer, and  $SO_4^{2-}$ ,  $NO_3^{-}$ ,  $NH_4^{+}$ ,  $Na^+$ ,  $Cl^-$ ,  $CH_3SO_3^{-}$ ,  $Mg^{2+}$ ,  $Ca^{2+}$ , and  $K^+$  using a particle-into-liquid sampler-ion chromatography technique. The results show the marine boundary layer (MBL) aerosol mass was dominated by non-sea-salt SO<sub>4</sub><sup>2</sup>followed by Na<sup>+</sup>, Cl, Org, NO<sub>3</sub>, and NH<sub>4</sub><sup>+</sup>, in decreasing importance; CH<sub>3</sub>SO<sub>3</sub>, Ca<sup>2+</sup>, and K<sup>+</sup> rarely exceeded their respective limits of detection. The  $SO_4^2$  aerosols were strongly acidic as the equivalent  $NH_4^+$  to  $SO_4^2$  ratio was only  $\sim 0.25$  on average. NaCl particles, presumably of sea-salt origin, showed chloride deficits but retained Cl typically more than half the equivalency of Na<sup>+</sup>, and are believed to be externally mixed with the acidic sulfate aerosols. Nitrate was observed only on sea-salt particles, consistent with adsorption of HNO<sub>3</sub> on non-acidic sea-salt aerosols, responsible partly for the Cl deficit. Dust particles appeared to play a minor role judging from the small volume differences between that derived from the observed mass concentrations and that calculated based on particle size distributions. Because  $SO_4^{2}$  concentrations in the study domain were substantial ( $\sim 0.5 - \sim 3$ µg/m<sup>3</sup>) with a strong gradient (highest near the shore decreasing with distance from land), and the ocean-emitted dimethylsulfide and its unique oxidation product, CH<sub>3</sub>SO<sub>3</sub>, were very low (i.e.,  $\leq 40$  parts per trillion and  $<0.05 \,\mu\text{g/m}^3$ , respectively), the observed  $SO_a^{2-}$  aerosols are believed to be primarily of terrestrial origin. Back trajectory calculations indicate sulfur emissions from smelters and power plants along coastal regions of Peru and Chile are the main sources of these SO<sub>4</sub> aerosols. However, compared to observations, model calculations appeared to underestimate sulfate concentrations based on an existing emission inventory. An up-to-date and comprehensive emission inventory currently being constructed will be tested to examine models' capability in predicting distributions of sulfate precursors and other emitted materials such as CO both in the MBL and the free troposphere by comparing to observations. Analysis of the role sea-salt particles play in in-cloud SO<sub>4</sub> production and in acidification of seawater by deposition will also be presented.
